Abstract
Quartz resonators are widely used for applications such as communication devices as key parts of frequency control and selection. Although main mode of quartz resonators which is thickness-vibration has remarkably stable frequency-temperature characteristics, in case couples with spurious mode at a given temperature, it shows large frequency fluctuation at the temperature.

So shape and size of quartz plate and electrodes have to be adjusted to avoid coupling with spurious modes. Because spurious problems are actualized so that downsizing demands increase, it becomes difficult to find out good design to meet them.

Then we are aimed at utilizing simulation in designing of quartz resonators effectively. However large-scale simulation environment is needed to improve calculation accuracy, it was a major hurdle.
In this project, we made calculation model from precise measuring of actual resonators and calculated by UV 2000 which has large-scale memory system. The result is compared to measured frequencies of main mode and spurious modes. As a result of resolving the calculation scale problem, we obtained adequate accuracy to predict coupling-temperature.

Keywords: large-scale simulation, finite element method, quartz resonator, frequency, coupling temperature
